

# 7 Markov Chains

For the Markov chain, the past and **the future are conditionally independent**. For the special case of random walk on an undirected network, the network structure is the key to determining the stationary distribution.

We can picture a Markov chain intuitively by imagining a system with *states* and someone randomly wandering around from state to state.

For many interesting Markov chains, the *stationary* distribution of the chain helps us understand how the chain will behave in the long run.

## 7.1 Markov property and transition matrix

A sequence of RVs  $X_0, X_1, X_2, \dots$  evolving over time. This is called a *stochastic process*.

Markov chains have a form of one-step dependence, allowing to do beyond IIDs but still have very convenient structure.

Markov chains widely used for simulations of complex distributions, via algorithms known as *Markov chain Monte Carlo (MCMC)*.

Markov chains live in both space and time: the set of possible states  $X_n$  is called *state*, and index  $n$  represents evolution of the process over *time*. The state space can be discrete or continuous, and time can also be discrete or continuous. We will focus on *discrete-state, discrete-time* Markov Chains with a *finite* state space.
